14 **Summary**
Introduction
HVACR (heating, ventilation, air conditioning and refrigeration) systems are responsible for keeping buildings, such as office premises, hospitals, data centers and others, air-conditioned and comfortable. A considerable amount of energy is consumed in HVACR systems. Proper use of variable-frequency drives (VFDs) in these systems will substantially reduce their energy consumption.

VFDs, along with many other types of electronics, cause a phenomenon known as power line harmonics. The advantages of using a VFD far outweigh the negative effects of harmonics, but it is important to be aware of harmonics, the potential problems they can cause, and the solutions that are available to mitigate those harmonics.

While this paper focuses on VFDs as a source of harmonics, it is important to note that VFDs are not the only source of harmonics in a system. However, VFDs are often the focus of harmonic calculation and mitigation conversations due to the fact that VFDs in HVACR applications may make up a significant portion of the overall building power consumption. Examples of VFDs in HVACR applications include pumps (chilled water, condenser water, hot water), fans (supply, return, exhaust, cooling tower), and compressors. Examples of other sources of significant harmonics include electronically commutated motor (ECM) powered fans, lighting systems, uninterruptible power supply (UPS) systems, and single-phase power supplies.

Harmonics appear on the voltage waveform due to electronic devices that draw current in a non-linear way. Harmonics are typically measured as a percentage value, called total harmonic distortion (THD). It is the ratio of the RMS (root mean square) harmonic content over the RMS value of the fundamental frequency. THD represents the percentage of deviation from the fundamental sinusoidal waveform. If the voltage or current does not contain any harmonics, the THD would be zero percent. As the amount of harmonics increases, the THD percentage increases as well.

There are a variety of industry standards used to identify an acceptable amount of harmonic distortion compared to a troublesome amount of distortion. For example, IEEE 519-2014 is used in the United States and some countries in Asia. There are also electromagnetic compatibility (EMC) standards for harmonics in Europe and Asia. These standards are written from the utilities’ point of view, thus they are intended to prevent customers from generating a level of harmonic distortion high enough to impact the power quality of neighboring customers on the electrical grid.

The word “harmonics” is a broad term and is used in many different industries. Unfortunately, certain electrical problems are incorrectly blamed on harmonics. These harmonics should not be confused with radio frequency interference (RFI), which occurs at much higher frequencies than harmonics. Power line harmonics are low-frequency, thus they do not interfere with wireless LAN signals, cellphones, FM or AM radios, or any equipment that is specifically sensitive to high-frequency noise. ABB offers a separate paper on disturbances caused by RFI (document number 3AUA0000222151).

Basics of harmonics
Voltage harmonics are the distortion of the voltage waveform. Likewise, current harmonics are the distortion of the current waveform. These distorted waveforms are difficult to quantify with a simple equation, thus a mathematical method is used (called a Fourier analysis) when discussing harmonics. This method determines the magnitude and frequency of many smaller sinusoidal waveforms that make up the distorted waveform seen at a facility. This allows the engineer to identify which are the most problematic individual harmonics and to provide corrective measures to reduce those harmonics.

As stated in the introduction, harmonics are often discussed in terms of a THD percentage. This percentage value describes how badly the waveform is distorted from a pure sinusoidal waveform. A waveform that is highly distorted will have a higher THD percentage value. The following two formulas are used to quantify the amount of
harmonics in a system. THD\(_v\) is the total harmonic distortion of the voltage waveform. THD\(_i\) is the total harmonic distortion of the current waveform. In both cases, the calculation is based on the ratio of the RMS harmonic content over the RMS value of the fundamental value. In other words, the more harmonic content, the higher the THD percentage.

\[
THD_v = \sqrt{V_2^2 + V_3^2 + V_4^2 \ldots V_n^2} \cdot 100\%
\]
\[
THD_i = \sqrt{I_2^2 + I_3^2 + I_4^2 \ldots I_n^2} \cdot 100\%
\]

While outside the scope of this paper, another important topic involving harmonics is to understand what THD\(_v\) and THD\(_i\) levels are acceptable for a building. Each system is unique and takes into account the size of a building’s load compared to the capacity of the utility, known as the short circuit ratio. Also, understanding where to measure the harmonics, known as the point of common coupling (PCC), is often a misunderstood concept. In short, the PCC is typically the point where the building’s network is connected to the electrical utility grid. Total Demand Distortion (TDD) is measured at the PCC in lieu of THD\(_i\). The TDD is typically used to evaluate harmonics for the entire building, while THD\(_i\) is used to evaluate harmonics for an individual device within the building.

**Causes of harmonic distortion**
Harmonics are caused by non-linear loads. Non-linear loads do not draw current sinusoidally from the utility. Examples of non-linear loads include VFDs, EC motors, LED lighting, photocopiers, computers, uninterruptible power supplies, televisions, and the majority of electronics that include a power supply. The most significant causes of harmonics in the building are typically non-linear, three-phase power, and the more power there is, the bigger the harmonic currents in the network will be.

The next section reviews the electrical characteristics of a VFD. This is to illustrate an example of a non-linear load. The most popular VFD design works by taking a three-phase AC line input voltage and rectifying the voltage through diodes. This turns the voltage into a smooth DC voltage across a bank of capacitors. The VFD then converts the DC back into an AC waveform for the motor in order to control the speed, torque and direction of the motor. The non-linear current is created by the three-phase AC-to-DC rectification.

**Problems caused by harmonic distortion**
High levels of harmonic distortion in a facility can create a wide range of problems. Some of the problems that may be encountered are:

- Premature failure and reduced lifespan of devices often occurs when overheating is present, such as:
  - Overheating of transformers, cables, circuit breakers and fuses
  - Overheating of motors that are powered directly across the line
- Nuisance trips of breakers and fuses due to the added heat and harmonic loading
- Unstable operation of backup generators
- Unstable operation of sensitive electronics that require a pure sinusoidal AC waveform
- Flickering lights

---

1. Pure sinusoidal current waveform with no harmonics
2. Current waveform with harmonics
The issues mentioned in the previous page are often hard to identify as harmonics-related problems. For example, we know that motors are designed to run almost to the point of overheating. Under normal operating conditions, placing one’s hand on a fully loaded motor may be too uncomfortable after a second or two. Thus, how would the typical building owner realize if that motor were running an extra ten degrees hotter due to harmonics? And that same owner most probably would not realize if the motor failed after six years due to harmonics, when that motor should have lasted 12 years. This example is just one of many hidden economic aspects tied to harmonics, which will be covered in the next section. It is important to note that this example was based on a motor that was powered across the line, thus exposed to a distorted waveform. VFDs essentially buffer a motor from power line harmonics, so motors powered from a VFD would not experience this power line harmonic phenomenon leading to premature failure.

**Economic issues caused by harmonic distortion**

Harmonics have an economic impact during all phases of a building’s lifespan. First, there is the upfront cost of either sizing equipment to handle harmonics, or investing in harmonic mitigation in the first place. Secondly, there are the day-to-day added costs due to the inefficiency of the system. Finally, there are the costs due to premature failure of equipment.

One way to deal with harmonics is to simply oversize portions of the electrical infrastructure within a building. Transformers and wire size may be upsized to handle the added harmonic content and heat. Backup generators also need to be oversized in systems with significant harmonic loading. There are multiple aspects to generator sizing. The generator has to be capable of handling the added harmonic current. Also, the generator’s voltage regulator has to be capable of handling the voltage distortion without causing unstable operation.

An alternative to paying for oversized equipment would be to invest in products that create less harmonics. Using a VFD as an example, lower-cost VFDs can draw 67 percent (or more) current than a moderate-cost VFD that includes a DC choke or input line reactor. The best solution is achieved with mitigation technologies that are able to mitigate the harmonics to below 5 percent. Investing in harmonic mitigation solutions is an alternate solution to oversizing the electrical infrastructure.

The day-to-day costs of harmonic-induced system inefficiencies are often hidden and overlooked. A transformer or motor that runs hotter means it is using energy in an inefficient manner, since energy is being used to create heat, instead of powering other loads in the building. The building’s HVAC system now operates at a higher capacity, thus consuming more power as it needs to remove the waste heat from the building.

The costs of failed equipment are not hidden. However, identifying those failures and costs as being related to harmonics is a challenge.

Addressing harmonics during the design phase allows for other parts of the electrical infrastructure to cost less (i.e. not oversized). Once harmonics are addressed, further long-term cost savings are achieved through higher efficiencies and longer-lasting equipment.

**Harmonics in critical facilities**

The previous sections of this document describe issues that may impact any building. However, there are certain industries that have to pay very close attention to power quality—and so pay close attention to harmonics—as uninterrupted performance of their HVAC systems is vital. Hospitals, data centers, and airports are the top three industries that are most often mentioned as critical facilities. Hospitals and airports have equipment that, if it were to fail, could put lives at risk. Data centers contain sensitive equipment...
that stores a vast amount of information and is expected to have continuous uptime. System designers should be aware of the impact of harmonics on any critical facility.

The next part of the paper talks about the power factor, which is an electrical component that is also affected by harmonics.

**Power factor**

Power factor is an electrical term used in the electrical industry. However, it is a term that can cause confusion because there are actually three different types of power factor: true power factor, displacement power factor, and distortion power factor. The equation on this page shows the relationship between these different power factor types. True power factor takes into account the displacement power factor (also known as \( \cos \phi \)) and distortion power factor (that is a function of the amount of harmonic current).

\[
p_{\text{true}} = \frac{p_{\text{avg}}}{V_{\text{rms}}I_{\text{rms}}} \cdot \frac{1}{\sqrt{1 + \left(\frac{THD}{100}\right)^2}} = p_{\text{disp}} \cdot p_{\text{dist}}
\]

The three most important takeaways on power factor for an engineer or building owner are:

- Some utilities charge fees to customers who have a poor power factor, and/or offer a cost reduction on the utility bills of customers who have a good power factor.
- Adding a VFD to a motor will improve the true power factor.
- VFDs that generate less harmonics will improve the true power factor better than a VFD with a higher harmonic footprint.
Different ways to mitigate harmonics

There are many ways to mitigate harmonics and there is no “one size fits all” solution. The table below compares the THD of various harmonic mitigation technologies, along with other comparisons.

* Valuations are based on ABB low harmonic drives
** System price considers VFD & installation costs

Six-pulse drive, no reactor
This would describe a standard six-pulse drive without any harmonic mitigation. This type of drive is used because of its lower cost and small footprint. This VFD design can be used as a reference point, since no mitigation technique is used. The exact current distortion varies based on the design, but values between 90 and 120 percent are typical.

It is important to note that there is a variation of this drive on the market that utilizes an undersized DC bus capacitor. This design makes the THD value look better, but it has a significant negative impact on THD, in the power system. This type of drive is very susceptible to overvoltage and undervoltage tripping due to line transients, sags and surges.

Six-pulse drive with 3–5% reactor

**Pros**
- Assuming physical space is available, a passive harmonic filter can be added after the drive is installed, if harmonics are determined to be a problem.
- Includes regenerative braking.
- Traditional harmonic mitigation method.
- One active filter can clean up the harmonics from multiple drives/loads.

**Cons**
- Leading power factor at light loads unless the filter’s capacitors are switched out of the circuit.
- Risk of resonances between the filter capacitors and other capacitors in the system.
- Low harmonic mode (5% THD) does not allow full speed control throughout the entire frequency range, as it can only modulate up to 93% voltage.
- No under voltage ride-through of power circuitry due to the lack of DC bus.
- Very large footprint.
- Significant number of points of failure.
- Optimal harmonic performance requires perfectly balanced AC power feed with little background distortion.
- Very difficult to retrofit in the field.
- Typically the most expensive solution.
- The filter becomes a single point of failure for harmonic mitigation. A filter failure could result in significant/immediate harmonic related issues within the system.

—

05 Six-pulse drive with 3–5% reactor

and through that, the drive decreases the harmonic current levels to 35–45 percent. ABB recommends this solution as a starting point for all drives used in HVAC systems. Then, if a harmonic calculation determines further reduction in the THD is required, upgrade to a better harmonic mitigation technology.

**Passive filters**
Passive filter solutions are additional filters that are added on the supply (line) side of the drive. Modern designs consist of an inductor-capacitor-inductor design that is tuned to target a specific harmonic frequency. The performance of passive harmonic filters varies from manufacturer to manufacturer, with some designs providing poor harmonic mitigation at partial loads, or when there is already existing voltage distortion on the building’s power supply. Typical performance of passive harmonic filters result in a current distortion between 5 and 10 percent.
Passive filters are known to create a leading power factor at partial loads. Most manufacturers offer an optional contactor that removes the filter’s capacitor banks at partial load. This contactor is highly recommended for any filters that could be powered from a generator source, as generators can become unstable when loads draw a leading power factor current. The capacitor in a passive harmonic filter has also been known to interact with other capacitors in an electrical network, such as the capacitors found in power factor correction banks, or the capacitors in a drive. These capacitor interactions can lead to nuisance electrical problems.

Passive filters may be offered separately as a stand-alone filter, provided in its own enclosure, meant to be wired next to the drive. Additionally, passive filters may also be provided by the drive manufacturer in the same enclosure as the drive. Supplying and mounting the filter separately requires additional coordination during the design and construction phase of a project. Coordination examples include:

- Space must be allocated for installation location of each filter.
- Budgets should include additional labor for installation and wiring of the filter.

- Care must be taken when installing the passive filter to a drive. There is a possibility to confuse passive filter with dV/dt filter, and then the filter is installed in the wrong side of the drive.
- Additional filter wiring must be completed if the drive includes a bypass. The filter should not be in the electrical path during bypass mode, thus the filter must be wired into the drive-only path, and not in the bypass path. This adds additional complexity that may not be understood by the installer.
- If the filter capacitor is to be switched off at partial load, a power source and additional wiring between the drive and the contactor coil will need to be provided, and the connections detailed for the installer.

Active filters
An active harmonic filter works like noise-cancelling headphones. The active filter takes measurements that detect the current distortion, and then supplies a counter-waveform to cancel out the distortion. The active harmonic mitigation is effective, normally achieving harmonic current distortion levels between 4 percent and 7 percent. There are several challenges in properly applying active harmonic filter solutions. They have a large footprint and require external current sensors.

Transformer, passive filter, drive rectifier and DC link

Current is quite smooth THD, 5–10%

Transformer, active filter, drive rectifier and DC link capacitors

Current quite smooth THD, 4–7%
These filters are sized to clean up a specified amount of harmonic current (Amps) from the system. Due to the large size and cost of active filters, they are normally installed for the building as a whole, or for a group of drives, and of course, this fixes the problem at that particular point, but it does not help devices inside the building or elsewhere that are affected by harmonics. There is also some risk with this solution as a single point of failure, because if this one filter fails, the harmonic levels seen upstream will increase significantly.

**Multi-pulse solutions**

Multi-pulse solutions are another method of mitigating harmonics. A standard drive is six-pulse, and low-voltage multi-pulse packages are typically 12-pulse or 18-pulse designs. There are 24-pulse designs and higher also available, but those are typically found on medium-voltage drives. The total number of rectifier diodes included in the package is the same as the “pulse” number. Multi-pulse packages have the largest footprint of all standalone harmonic-mitigating solutions because of all the hardware required. An 18-pulse package for example, includes a six-pulse drive, 12 additional diodes, balancing reactors, (18) fuses, special pre-charge circuitry, a considerable amount of power wiring connecting these components together, and a large transformer. A relatively “small” 23-amp, 18-pulse package is approximately the same size as a refrigerator, due to the transformer and all of the hardware that makes up that package. An 18-pulse package starts out by taking three-phase input voltage, and uses the phase shifting transformer to create a total of (nine) phases. The VFD draws power across (nine) phases instead of (three), resulting in a smaller amount of current drawn from each of those (nine) separate phases. The current distortion of an 18-pulse is between 5 percent and 6 percent. The current distortion of a 12-pulse is between 10 percent and 12 percent.

The multi-pulse current distortion values listed above assume perfectly balanced voltage applied to the drive. A small, 2-percent voltage imbalance to the drive can result in a 50-percent increase in its current distortion. Also due to all the additional hardware, these packages are among the least energy-efficient packages on the market. Multi-pulse packages are one of the original solutions for harmonic mitigation that dates back over 20 years. But due to size, and their requirement for perfectly balanced power, this harmonic mitigation technology is becoming less common.
Active front end
In an active front end (AFE) drive, the rectifier consists of insulated gate bipolar transistor (IGBT) devices instead of diodes. The AFE drive also includes a built-in LCL (inductor-capacitor-inductor) filter. The IGBT-based rectifier is controlled in a way that allows the drive to draw nearly pure sinusoidal current. The LCL filter helps remove any high-frequency noise created by the IGBT switching. An LCL filter is generally preferred over a less effective LC filter. With the combination of an IGBT rectifier and LCL filter, ABB AFE drives have a current distortion between 3 percent and 5 percent, and may also be known as ULH (ultra-low-harmonic) drives.

The AFE is the most compact of any solution that can achieve a current distortion below 5 percent. The power factor is unity, which means that it uses the least amount of reactive current possible. Also, AFE drives have excellent harmonic performance at partial loads. Installation of an AFE drive is simple, as they are traditionally built as a single piece of equipment with line input terminals and motor output terminals. Due to the active control of the IGBT front end, the AFE drive is more immune to voltage imbalance than any other harmonic mitigation solution.

Other mitigation technologies
There are other ways to mitigate harmonics, such as drives with an undersized DC bus capacitor and matrix technology drives, but ABB does not recommend using them. A previous section on six-pulse drive, no reactor, references drives with undersized DC bus capacitors. The paragraph below briefly covers matrix drives.

Matrix technology consists of drives that have nine bi-directional IGBTs and no DC bus capacitors, which means that input AC voltage is converted directly to an output AC voltage. While the concept sounds promising, there are significant technical limitations to the matrix drive. Matrix drives are unable to provide full output voltage, while providing optimal harmonic mitigation. When a matrix drive is configured to have optimal harmonic mitigation (almost as good as an AFE drive), the output voltage is limited to only 87 or 93 percent. Limiting the voltage to the motor would cause its motor to draw more current at full speed and full load, leading to an overheated motor. The output voltage can be configured to go higher than 87 percent, but then the current distortion also needs to increase. The matrix solution allows either good harmonic mitigation, or full control of the output voltage, but not both at the same time. The typical current distortion level is from 5 percent to 13 percent, depending on whether it is configured to provide limited or full output voltage.
It is important to pay attention to harmonic levels in the network, since it will pay you back in the long run. THD$_V$ is the total harmonic distortion of the voltage, and THD$_I$ is the total harmonic distortion of the current. THD$_V$ has the greatest impact on the end-users’ power quality. However THD$_I$ is the easiest way to compare different harmonic mitigation solutions. The current harmonics (THD$_I$) are responsible for creating the voltage harmonics (THD$_V$), and thus it is acceptable that in this document, we only compared different mitigation technologies based on current harmonics (THD$_I$). Harmonic distortion creates a variety of problems within a building, but the most common problem is additional heat. As devices run hotter, they run less efficiently and are prone to premature failure.

There is no “one size fits all” solution in the mitigation of harmonics. However, there are rules of thumb that can help provide some direction for the typical cases with harmonics.

- On projects where drives make up less than 30 percent of the building transformer’s capacity, using all six-pulse drives with 5 percent impedance will be acceptable.
- On projects with more drive loading, a combination of six-pulse drives with 5 percent impedance (on the smaller drives) and AFE drives (on the larger drives) will be the optimal system solution.

A computer-simulated harmonic analysis is recommended for any project that has a considerable amount of non-linear loading. The harmonic analysis will identify the harmonic levels and show the impact of upgrading to additional harmonic mitigation (such as an AFE), if required. ABB can help with a harmonic analysis of your building or project.
